8 **Abstract**

9 There exist millions of species on Earth, all originating from a common  
10 ancestor billions of years ago. The field of phylogenetics uses heritable  
11 material to determine which species are closest related and what are the  
12 mathematics that shape speciation.

13 In Bayesian phylogenetics, a DNA/RNA/protein alignment is used to  
14 infer a distribution of phylogenies and parameter estimates. To do so,  
15 we use assumptions that may be biologically unrealistic, but may give  
16 tolerable errors.

17 Contemporary inference assumes that speciation never co-occurs.

18 Here we show the error we make in our inference, when nature has  
19 varying degrees of co-occurring speciation.

20 **Keywords:** computational biology, evolution, phylogenetics, Bayesian anal-  
21 ysis, tree prior

# 1 Introduction

- There are many contemporary tools that provide the possibility to infer a phylogeny from genetic data (DNA, RNA, proteins). A popular Bayesian phylogenetic tool is called BEAST (Drummond & Rambaut 2007) and its cousin BEAST2 (Bouckaert *et al.* 2014).
- BEAST is very flexible, providing the user with the option to set up all possible phylogenetic priors (e.g. site/clock/speciation model).
- However, currently available priors can be not suitable to analyze some specific datasets. With this work we aim to test whether or not the implementation of a new prior model is beneficial to study a specific kind of diversification process.
- BEAST2 gives us the possibility to introduce new tree priors to infer phylogenies based on different assumptions on how the speciation process takes place.
- One of such speciation processes is the multiple birth hypothesis, a new model (described below) and thus currently absent in BEAST.
- The Multiple birth hypothesis can be useful to explain a phenomenon that has always puzzled evolutionary biologists: what are the drivers of the diversification processes for those phylogenies that show an impressive amount of speciation events in relatively short times? The (constant-rate) birth-death (BD) model embodies the common assumption that only a single speciation event can occur at any given time. The multiple-birth-death (MBD) model relaxes this assumption, allowing events in which large-scale environmental changes lead to a great number of species in relatively short time intervals. Such a hypothesis may be a better fit to

describe the burst in systems like cichlid fish diversification in the African Great Lakes: Malawi, Tanganyika and Victoria (Janzen *et al.* 2016, Janzen *et al.* 2017).

- However, it may be that current BD tree priors are good enough at detecting such events, with a (preferred) lower level of complexity. If this is the case one should always be more keen to adopt the simplest model.
- Here we present our study with the aim of exploring when using a more complex MBD tree prior is warranted. To do so, we simulate phylogenies using the MBD process, with varying degrees of that process. To be explicit, we define that degree,  $s$ , as the number of extinct and extant species created during a co-occurring speciation event,  $n_{\mathbb{M}}$ , from the total number of extinct and extant species:

$$s = \frac{n_{\mathbb{M}}}{n_{\mathbb{M}} + n_{\mathbb{B}}} \quad (1)$$

Here,  $n_{\mathbb{B}}$  is the number of extinct and extant species created during a default single-birth speciation event.

From such phylogenies with different degrees of  $s$ , we measure the inference error we make today, would nature follow such a phylogeny. The inference error we make today is caused by the assumption of a BD process and by inherent noise in this inference.

We have the hypothesis  $\mathcal{H}_1$  that, for a higher  $s$ , the inference error  $e$  will increase:

$$e = f(s) \quad (2)$$

Where  $f$  is a monotonously increasing function of unknown shape.

Figure 1: Hypothesis 1: we expect the error made be correlated to the number of species created by the multiple-birth process over the total number of species created

68 The MBD process has multiple components, that may cause different val-  
69 ues of  $e$  for identical values of  $s$ .

70 One MBD component that may cause different values of  $e$  for identical  
71 values of  $s$  is the MBD regime: which can be many modest multiple-  
72 speciation events, or few intense ones. As we have no prior expectations,  
73 we have the (null) hypothesis,  $\mathcal{H}_7$ , that the MBD regime has no effect on  
74  $e$ .

75 Another MBD component that may cause different values of  $e$  for identical  
76 values of  $s$  is the effect of extinction. As extinctions will hit lineages  
77 created by both speciation processes equally, and we have no additionaly  
78 prior expectations, we have the (null) hypothesis,  $\mathcal{H}_2$ , that extinction has  
79 no effect on  $e$ .

80 Another MBD component that may cause different values of  $e$  for identical

Figure 2: Hypothesis 7: there is no difference in inference errors if the MBD process generates many species in many modest MB events or few intense MB events

Figure 3: Hypothesis 2: the effect of extinction rates is neutral

81 values of  $s$ , is the timing of a multiple-birth event: be it close to the crown  
 82 age or close to the present. Compared to a late multiple birth event, an  
 83 early multiple birth event may have a longer-lasting effect (as the next  
 84 speciation event will be later), but it will create less new species, as there  
 85 are still fewer taxa. As we have no prior expectations, we have the (null)  
 86 hypothesis,  $\mathcal{H}_3$ , that the timing of multiple-birth events has no effect on  
 87  $e$ .

Figure 4: Hypothesis 3: the timing of a multiple birth event has no effect.

88 Another MBD component that may cause different values of  $e$  for identical  
 89 values of  $s$ , is the number of taxa in a phylogeny. As there is no diversity  
 90 dependency in any of the processes and we have no further prior expecta-  
 91 tions, we have the (null) hypothesis  $\mathcal{H}_5$ , that the number of taxa has no  
 92 effect on  $e$ . As a higher number of taxa increases the information content  
 93 in a phylogeny, we have hypothesis  $\mathcal{H}_6$  that the variance in  $e$  decreases.

Figure 5: Hypothesis 5: the number of taxa does not have an effect on the error being made

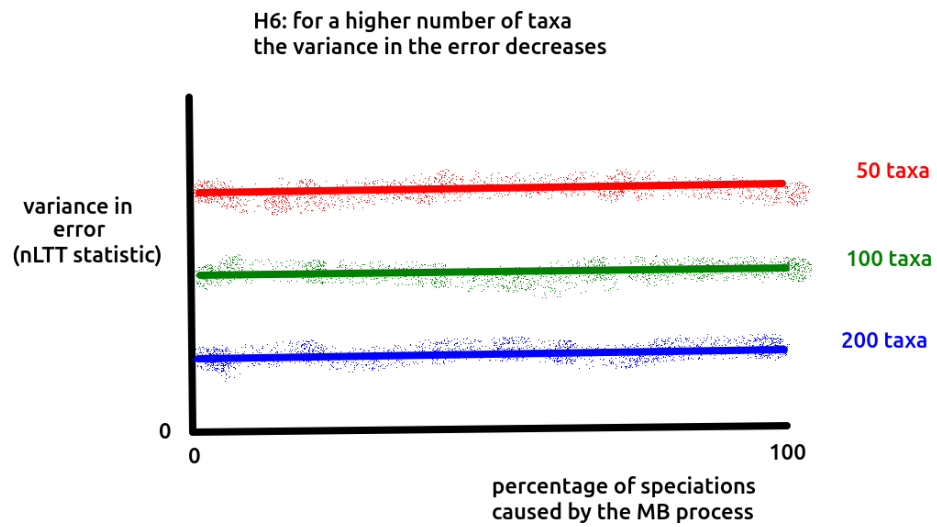

Figure 6: Hypothesis 6: for a higher number of taxa the variance in the error decreases

## 94 2 Methods

### 95 2.1 Model

- 96 • Current phylogenetic tools assume that only a single speciation event can  
97 occur at any given time. While this assumption is useful to construct  
98 a wide variety of successful models (e.g Maddison *et al.* 2007, Valente  
99 *et al.* 2015, Etienne *et al.* 2012, Etienne *et al.* 2014), they disallow for  
100 environmental changes that trigger speciations in multiple clades at a same  
101 point in time.
- 102 • In the MBD model, parameters  $\lambda$  and  $\mu$  correspond, respectively, to the  
103 common per-species speciation and extinction rates present also in the  
104 standard BD model. Additionally, MBD relies on two additional param-  
105 eters. Parameter  $\nu$  is the rate at which an environmental change is trig-  
106 gered. When such event is triggered, all species present in the phylogeny  
107 at that moment have a probability  $q$  to speciate at that time, which is  
108 independent on  $\lambda$ . Polytomies are not allowed in such process as each  
109 species can speciate only once at the time.
- 110 • It is also possible to write down a likelihood function for such processes  
111 as in Laudanno 2018.

### 112 2.2 Simulations

- 113 • To prove our hypothesis we simulate two twin datasets. All the simulations  
114 are produced in continuous time, using the Doob-Gillespie algorithm.
- 115 • We start simulating  $N_S = 1000$  MBD trees, with either 50, 100 and 200  
116 taxa.
- 117 • From each MBD tree, a DNA sequence alignment is simulated. For each

sequence alignment we then perform a Bayesian analysis to recover a posterior distribution of trees, each composed of  $N_P$  phylogenies. Such analysis is performed using the 'pirouette' package (Bilderbeek 2018) to call the BEAST2 tool suite from R. We let the Bayesian analysis assume a BD prior in both cases, to investigate the extent of the error we make under this assumption.

- For each tree generated under the MBD model we aim to generate a "twin" tree under the BD model. With the word "twin" we denote a tree generated starting from the respective MBD tree, in order to perform a fair comparison with it. This operation has to be done, because we want to compare two trees that are generated by different processes. To do so we infer the parameters  $\lambda_{BD}$  and  $\mu_{BD}$  from the MBD maximizing the likelihood under a BD model. To perform this operation we use the function "bd.ML" from the package "DDD" (Etienne *et al.* 2012).
- We then exploit such parameters to generate a BD tree using the function "tess.sim.taxa.age" from the package "TESS" (Hhna 2013). We simulate the tree in such a way the new tree has the same number of tips and the same crown age as the MBD tree. We furthermore require that the BD tree conserve the topology of the MBD tree. We have hypothesis H4 that, compared to the MBD trees, the error will be less in the BD twin tree. The difference between the errors made in MBD and twin BD trees indicates the impact the MBD process has on the error we make in inference using a contemporary BD prior.

We want the MBD and twin BD trees to contain the same amount of information, i.e. the same number of DNA mutations and the same number of taxa at the present:

Figure 7: Hypothesis 4: compared to the MBD trees, the error will be less in the BD twin tree

$$m_{MBD} = m_{BD} \quad (3)$$

144 The expected number of mutations  $m$  of a phylogeny with crown age  $-T$   
 145 (with  $T > 0$ ) in fact is given by [RJCB: So one of use likes '-T', the  
 146 other likes 'T'. How to resolve this? ]

$$m = L \cdot \rho \cdot \int_0^T n(t) dt \quad (4)$$

147 where  $L$  is the number of DNA nucleotides,  $\rho$  is the per-site per-species  
 148 mutation rate and  $n(t)$  the number of species at each time.

149 The parameter we'll tune is  $\rho$  ... [RJCB: elaborate here :-)]

150 Since we cannot know  $n_{BD}(t)$  before running simulations we need to re-  
 151 place it with a proxy. For this reason we will use the average number of  
 152 species in time according to the BD model. It's well known that this is  
 153 equal to [GL: insert proper citation]

$$< n_{BD} > (t) = n_0 \cdot e^{(\mu_{BD} - \lambda_{BD})t} \quad (5)$$

where  $n_0 = n_{BD}(-T) = n_{MBD}(-T)$  is the initial number of species at the crown age. From 3, 4 and 5 follows:

$$m_{MBD} = L \cdot \rho \cdot \int_0^T < n_{BD} > (t) dt = L \cdot \rho \cdot n_0 \cdot \left[ \frac{e^{(\mu_{BD} - \lambda_{BD})T} - 1}{\mu_{BD} - \lambda_{BD}} \right] \quad (6)$$

If we set  $\mu_{BD} = \mu_{MBD}$  and reverse this relation we can extrapolate the value of  $\lambda_{BD}$  to use to generate BD trees.

- We explained how we set the parameters for each twin BD tree. Using this rules we generate a BD dataset. We repeat the analysis, producing alignments for each tree and subsequently using BEAST to produce a posterior for each of them.

## 2.3 Measuring the inference error

- So far we have simulated two datasets of trees under the two models:  $\{T_i^{BD}\}_{i=1}^{N_S}$  and  $\{T_i^{MBD}\}_{i=1}^{N_S}$ . We used them to generate a dataset of alignments for each model:  $\{X_i^{BD}\}_{i=1}^{N_S}$  and  $\{X_i^{MBD}\}_{i=1}^{N_S}$ . From each dataset we produced a posterior distribution from a BD prior:  $P_i(\theta|X_i^{BD}, BD)$  and  $P_i(\theta|X_i^{MBD}, BD)$ . **[GL: 1) We might want to rename the models, e.g. BD = (0) and MBD = (1). These names with capital letters are too big and ugly; ] [RJCB: I would strongly prefer MBD and BD, as I feel replacing the big ugly capital letters by short pretty numbers hurts readability even more ]**
- To compare the results for the two models we measure the inference error

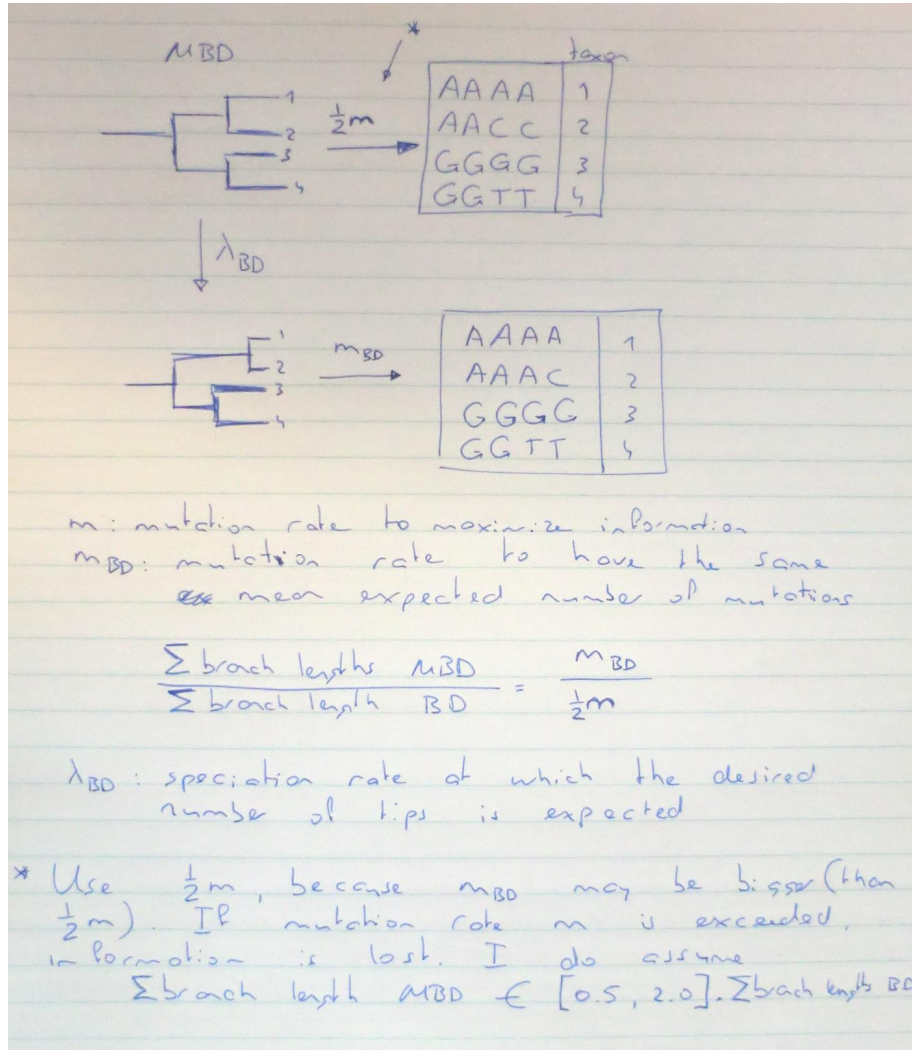

Figure 8: How to create twin trees and alignments. From a focal MBD tree, a twin tree is produced as such: (1) estimate the  $\lambda_{BD}$  to get the same expected number of tips, (2) simulate a BD tree with that amount of tips (discard trees with different number of tips), (3) estimate a mutation rate to get an alignment with the same expected number of mutations, (4) simulate alignments with that amount of mutations (discard those that don't, the picture shows an alignment that should be discarded)

using the nLTT statistic between known/true tree and posterior/inferred trees (Janzen 2015). To obtain such statistics the procedure is the following:

- From each tree  $T_{i,j}^M$  (with  $j = 1, \dots, N_S$ ) belonging to the posterior  $P_i(\theta|X_i^M, BD)$  and relative to the model  $M$ , we extrapolate the lineage-through-time (LTT), in other words we measure the number of species as a function of time  $n_{i,j}(t)$ . To allow a comparison we normalize dividing by the maximum number of species of each tree, i.e. the number of tips at the present  $N_{i,j}(t) = \frac{n_{i,j}(t)}{n_{i,j}^{max}}$ . We then define the nLTT measure as

$$nLTT_{i,j} = \int_0^T |N_{i,j}(t) - N_{T_i}| dt$$

[GL: I am running out of letters :(] [RJCB: Haha! I suggest to use the same equation and symbols as equation 1 in the nLTT article of Janzen, Hoehna and Etienne, 2015: ]

$$\Delta nLTT = \int_0^1 |nLTT_1(t) - nLTT_2(t)| dt$$

## 2.4 Model selection

We simulate alignments using the simplest nucleotide substitution model (JC69), the simplest clock model (strict). It is thus imminent to assume these models in our Bayesian inference. Nevertheless, the phylogeny the alignment was based on, could have followed either an MBD or BD tree model, where we in both cases assume a BD tree model. This will have an unknown effect on our inference: it may theoretically be that an MBD model generates (a tree that generates) an alignment in which a different site and/or clock model is favored.

We investigate this by measuring if the generative model (with the simplest

nucleotide substitution and simplest clock model) is indeed selected to be the best fitting model. To be precise, we look at the model with the highest marginal likelihood (also called evidence MacKay & Mac Kay 2003),  $f(D|M)$ , which is the probability of the data  $D$  given model  $M$ . In the context of this research,  $D$  consists of the DNA alignment, and  $M$  is the combination of site, clock and tree models.

To estimate the marginal likelihood, we use an algorithm named nested sampling Skilling *et al.* 2006. Nested sampling is attractive to use in a phylogentic context, as it gives a good estimation, requires little tuning Russel *et al.* 2018. Nested sampling is available as a BEAST2 package and can be used by babette Bilderbeek & Etienne 2018.

The nested sampling algorithm stops its run when the marginal likelihood estimation error reaches below a certain tolerance. Similar to Russel *et al.* 2018, we use a (relative) error tolerance  $\epsilon$  of  $10^{-13}$ , 1 particle to explore the parameter space and 100 active points. To achieve the latter, we use the MCMC chain length  $L_c$  of 1M (as also used in the parameter estimates), and a sub-chain length  $L_{sc}$  of 10K.

The models we use in our model comparison are the four combinations of two site models and two clock models. We use the JC69 site model, which is the (generative and) simplest model and GTR, the site model with most degrees of freedom. For the clock models, we use the strict clock model, which is the (generative and) simplest clock model, and the RLN clock model. **[RJCB: Could also just be all site models and clock models = 8 models]**

From these four marginal likelihood estimates, we calculate the weight of the generative model and plot this in figure 2. We do this for both the alignments derived from the MBD tree and the BD twin tree. We expect

223 that the generative model has the heighest weight in both the MBD and  
 224 BD alignments. We expect this weight to be higher in the BD alignments.

	Description
$e$	Inference error
$n_{\mathbb{M}}$	Number of extinct and extant taxa created by a multiple-birth event
$n_{\mathbb{B}}$	Number of extinct and extant taxa created by a single-birth event
$s$	Extent/strength of the multiple birth process
$L_c$	MCMC chain length
$L_{sc}$	MCMC sub-chain length
$\epsilon$	relative error tolerance in marginal likelihood estimation

Table 1: Overview of the symbols.

Symbol	Expectation	Figure
$\mathcal{H}_1$	For a higher $s$ , $e$ will increase monotonously	1
$\mathcal{H}_2$	Extinction rates have no effect on $e$	2
$\mathcal{H}_3$	The timing of multiple-birth events has no effect on $e$	3
$\mathcal{H}_4$	An MBD tree will have a higher $e$ than its twin BD counterpart	4
$\mathcal{H}_5$	The number of taxa has no effect on $e$	5
$\mathcal{H}_6$	A higher number of taxa decreases the variance in $e$	6
$\mathcal{H}_7$	The MBD regime has no effect on $e$	7

Table 2: Overview of the symbols.

	Value(s)
$L_c$	$10^6$
$L_{sc}$	$10^4$
$\epsilon$	$10^{-13}$

Table 3: Overview of the simulation parameters.
